*Accepted 4 July 1988*

### Summary

Sectioning the first four pairs of spinal nerves prevents the large increase in circulating catecholamine concentrations seen in Atlantic cod swimming at their critical velocity ( $U_{crit}$ ). There is also a significant reduction in the swimming performance of the fish. To test whether this reduced performance results from the lack of increase in plasma catecholamine levels or from the fact that other organs are also denervated by the operative procedure, a mixture of adrenaline and noradrenaline was infused into swimming, denervated fish. This caused a significant increase in their  $U_{crit}$ . It is concluded, therefore, that the rise in plasma catecholamine levels seen in Atlantic cod swimming at their maximum sustainable velocity enhances the swimming performance of these fish.

### Introduction

There are a number of ways in which circulating catecholamines could enhance the supply of oxygen to the active muscles in exercising fish and thus improve the animals' swimming performance. In resting rainbow trout in well-aerated water, approximately 40% of secondary lamellae are not perfused with blood (Booth, 1978) and, even in those lamellae that are perfused, up to 20% of the blood may be in basal channels which are probably nonrespiratory (Tuurala *et al.* 1984). Adrenaline increases interlamellar recruitment *in vivo* and *in vitro* (Booth, 1979; Holbert *et al.* 1979) and an increase in perfusion pressure (which could be mediated by catecholamines) causes inter- and intralamellar recruitment *in vitro* (Farrell *et al.* 1979, 1980). During intralamellar recruitment a greater proportion of blood perfuses the central lamellar spaces, i.e. there is a move away from the basal channels. There may, therefore, be a thinning of the epithelium of the lamellae, thus reducing the diffusion distance between blood and water. It has also

Key words: *Gadus morhua*, teleosts, catecholamines, swimming performance.

been suggested that adrenaline increases the permeability of the gills to oxygen (Isaia, 1984), although direct experimental evidence is lacking.

There are, therefore, a number of mechanisms by which plasma catecholamines could enhance oxygen transfer across the gills. In fact, addition of adrenaline to the perfusate does increase the difference in the partial pressures of oxygen between arterial and venous blood ( $P_{aO_2} - P_{\bar{v}O_2}$ ) (Wood *et al.* 1978) and oxygen uptake (Perry *et al.* 1985) in isolated, head preparations of rainbow trout perfused with saline. It has recently been demonstrated that there are modest increases in the levels of plasma catecholamines in rainbow trout swimming to apparent exhaustion (Butler *et al.* 1986). However, as these authors point out, the concentration of adrenaline is at least an order of magnitude lower than that used in the *in vitro* studies mentioned above. It may not, of course, be justifiable to extrapolate from *in vitro* observations to the whole animal, as any number of other mechanisms in the whole animal could influence the effect of catecholamines (Butler *et al.* 1986).

It is known that environmental hypoxia and damage to the gills can reduce swimming performance in fish (Jones, 1971; Bushnell *et al.* 1984; Duthie & Hughes, 1987). So, if plasma catecholamines do play an important role in providing an increased oxygen supply to the active muscles during exercise, particularly by enhancing gas exchange, then preventing their release should impair aerobic swimming performance.

The object of the present study was to test this possibility in the Atlantic cod, *Gadus morhua*, by determining the effect of surgically preventing the release of catecholamines on the swimming performance of the fish. In case the operation had other effects, in addition to preventing the release of catecholamines, swimming performance was also determined in these fish while infusing a mixture of adrenaline and noradrenaline.

### Materials and methods

Data were obtained from 25 Atlantic cod, *Gadus morhua*, of either sex and with a body mass of 380–920 g and length of 35–46 cm. They were captured off the Swedish west coast, kept in recirculated, aerated sea water at 10–12°C in the aquarium of the Zoological Institute in Göteborg and were used within 1 week of capture.

The fish were anaesthetized initially in tricaine methane sulphonate (Sigma) ( $100 \text{ mg l}^{-1}$ ) in sea water until ventilatory movements ceased. They were then transferred to an operating table and sea water containing the anaesthetic (approximately  $50 \text{ mg l}^{-1}$ ) was continuously pumped over the gills during the operation.

In some fish the head kidney was denervated by making incisions dorsally on both sides of the midline and sectioning spinal nerves 1–4 close to the cranium or vertebral column (Nilsson *et al.* 1976). These authors have shown that this procedure prevents the large release of catecholamines into the circulation in

response to 'stress'. In the remaining fish (sham-operated fish) incisions were made in the skin and muscles, and spinal nerves 1–4 were identified but not sectioned. In all fish a catheter (PE 50) was implanted into the afferent artery of the third gill arch for the measurement of ventral aortic blood pressure and heart rate and for the sampling of blood. The catheter was passed through the upper part of the operculum and sutured to the skin. It was filled with heparinized (approximately 50 i.u. ml<sup>-1</sup>) 0.9% NaCl and attached during the experiment to a Statham P23 pressure transducer connected *via* a three-way tap to a Grass polygraph recorder. In some fish that had undergone denervation of the head kidney, a polyethylene catheter (i.d. 0.4 mm, o.d. 0.8 mm) was introduced into the gonadal vein for the infusion of catecholamines.

Fish were allowed to recover from the operation for at least 24 h before any experiment, during which time the effects of surgery and anaesthesia wore off and the cardiovascular variables stabilized (see Smith *et al.* 1985). Some fish recovered in holding tanks whereas others recovered in a Blazka-type water channel (see Axelsson & Nilsson, 1986, for details). All fish were transferred to the water channel at least 3 h before the commencement of an experiment to give them time to recover from the stress of handling. The water in the experimental tube was fully aerated and continuously replaced at a rate of 2 l min<sup>-1</sup> from the main seawater system. The temperature was 10–12°C during all experiments.

In an initial series of experiments, critical swimming velocity,  $U_{crit}$ , (Brett, 1964) was determined for 17 intact fish (i.e. fish that had undergone no operative procedure) as described by Butler *et al.* (1986).  $U_{crit}$  was uncorrected for the presence of the fish in the channel (see Jones *et al.* 1974, for a discussion). In nine of these fish, the head kidneys were subsequently denervated and the remaining eight underwent sham operations. Their  $U_{crit}$  was determined again, but this time heart rate and ventral aortic blood pressure were monitored continuously and 0.6 ml of blood was removed from the fish when at rest, before swimming and at  $U_{crit}$  (see Butler *et al.* 1986, for details). This mixed venous blood was analysed for partial pressure and content of oxygen ( $P\bar{v}_{O_2}$  and  $C\bar{v}_{O_2}$ , respectively), pH ( $pH\bar{v}$ ), haematocrit, and levels of lactate, plasma adrenaline and noradrenaline.

In a subsequent series of experiments, the head kidney was denervated in eight fish. Heart rate and ventral aortic blood pressure were monitored and blood samples (0.45 ml) were taken from the fish at rest and while swimming at  $U_{crit}$ . In four fish a mixture of adrenaline and noradrenaline (15–20  $\mu\text{mol l}^{-1}$  adrenaline, 10  $\mu\text{mol l}^{-1}$  noradrenaline in saline) was continually infused, by a precision pump (Braun Limited), into the gonadal vein after 10 min of swimming in an attempt to simulate the levels reached in sham-operated fish swimming at  $U_{crit}$ . The fish were allowed 3 h to recover before being made to swim again while saline was infused into the gonadal vein. In the other four fish, saline was infused during the first swimming bout and the catecholamines were infused during the second bout.

It has been reported that the concentrations of plasma catecholamines remain unchanged in cod during moderate exercise (Axelsson & Nilsson, 1986), and it was found in the present study that if a high level of catecholamine infusion was made

during the early stages of the swimming bout, swimming performance was reduced. Thus, infusion was at a low rate ( $4 \mu\text{l min}^{-1}$ ) initially and then increased progressively (to  $20 \mu\text{l min}^{-1}$  and then to  $40 \mu\text{l min}^{-1}$ ) so that the desired level of catecholamines was reached towards the end of the swimming bout. The timing of the change from one infusion rate to another was dependent on the assumed swimming ability of the fish (which was easier to estimate when saline was infused first).

Ventral aortic blood pressure was measured with a Statham P23 pressure transducer connected to a Grass polygraph recorder system model 7D. Mean pressure was determined as diastolic + one-third pulse pressure. Heart rate was obtained from the pulsatile pressure signal *via* a Grass 7P44 tachograph unit. Partial pressures of oxygen in water and prebranchial (venous) blood and pH ( $\text{pH}\bar{v}$ ) in the blood were determined by an appropriate Radiometer electrode and a PHM73 blood gas analyser. Oxygen content in the blood was measured by the method described by Tucker (1967), using distilled water at  $0^\circ\text{C}$  equilibrated with  $\text{O}_2$  for calibration, and haematocrit was determined with a Wifug microhaematocrit centrifuge. Plasma lactate was assayed enzymatically using a Sigma kit (no. 826-UV) and a Perkin-Elmer Lambda 3 spectrophotometer.

The levels of adrenaline and noradrenaline in plasma were measured using ion-pair, reversed-phase high performance liquid chromatography (HPLC) with electrochemical detection. The sample preparation and analysis were performed basically as described by Ehrenström & Johansson (1985, 1987). Blood samples ( $200 \mu\text{l}$ ) were immediately added to  $20 \mu\text{l}$  of a mixture of  $0.2 \text{ mol l}^{-1}$  EGTA and  $0.2 \text{ mol l}^{-1}$  glutathione and centrifuged. The plasma was removed and stored at  $-20^\circ\text{C}$  for no longer than 1 week. Such storage has no effect on the levels of catecholamines (Butler *et al.* 1978). The plasma samples ( $40\text{--}150 \mu\text{l}$ ) were deproteinized by addition of  $0.2 \text{ mol l}^{-1}$  perchloric acid (PCA) to give a total volume of 1.15 ml. After addition of an internal standard (3,4-dihydroxybenzylamine hydrobromide, DHBA;  $600 \text{ pg}$  in  $50 \mu\text{l}$  of  $0.1 \text{ mol l}^{-1}$  PCA), the samples were vortex-mixed for a few seconds and centrifuged in a Sigma model 3K-2 centrifuge at  $4280 g$  for 10 min at  $4^\circ\text{C}$ . The supernatant ( $1.0 \text{ ml}$ ) was transferred to tubes containing 10 mg of acid-washed alumina (chromatographic alumina, Sigma no. A-1772),  $25 \mu\text{l}$  of 10% EDTA and  $25 \mu\text{l}$  of 1.5% glutathione. After addition of  $600 \mu\text{l}$  of Tris buffer ( $2.0 \text{ mol l}^{-1}$ ,  $\text{pH} 8.6$ ), the samples were vortex-mixed and the catecholamines allowed to adsorb onto the alumina for 30 min in a rotary mixer. The supernatant was aspirated off, the alumina was washed five times with 1 ml of chilled, deionized and filtered ( $0.45 \mu\text{m}$  membrane filters, Millipore) water and the catecholamines were eluted with  $100 \mu\text{l}$  of  $0.1 \text{ mol l}^{-1}$  PCA. The eluates were transferred to  $0.25 \text{ ml}$  polyethylene tubes (Eppendorf), capped and stored at  $-20^\circ\text{C}$  until analysis by HPLC. Recoveries of standard catecholamine samples treated in the same fashion were estimated (70–85%) and subsequent calculations were corrected for losses in the purification procedure.

The samples were analysed with a system consisting of an LKB HPLC pump and controller (models 2150, 2152, respectively) connected to a Waters amperometric

detector (model M460). The electrochemical cell was a Bioanalytical systems dual glassy carbon cell with a Ag/AgCl reference electrode (model RE-1). A Rheodyne injection valve (model 7125) equipped with a 20  $\mu\text{l}$  loop was used for injection of samples onto the HPLC column. This consisted of a Supelco 7.5 cm  $\times$  4.6 mm analytical column (Supelcosil, 3  $\mu\text{m}$  RP C<sub>18</sub> silica particles). The mobile phase consisted of 93.3 mmol l<sup>-1</sup> sodium acetate, 11.34 mmol l<sup>-1</sup> citric acid, 70 mg l<sup>-1</sup> 1-heptanesulphonic acid and 10 mg l<sup>-1</sup> EDTA (pH 5.25). The separation of adrenaline and noradrenaline was completed in less than 4 min at a flow rate of 1.5 ml min<sup>-1</sup>. The output from the detector was displayed on a Shimadzu data processor (Chromatopac model C-R3A). This system was sufficiently sensitive to detect 0.1–0.5  $\times 10^{-9}$  mol l<sup>-1</sup> catecholamines (1–5 pg per injection) using 40–150  $\mu\text{l}$  of plasma.

Mean values are expressed  $\pm$  s.e. of the mean. The Wilcoxon's sign rank test for paired samples or the Mann-Whitney U-test were used (both as two-tailed tests, except where indicated) and the level of significance was set to  $P < 0.05$ .

### Results

The effects of denervating the head kidney on the measured variables at rest, while swimming at  $U_{\text{crit}}$  and upon  $U_{\text{crit}}$  itself are given in Table 1. With the exception of plasma lactate concentration, which was significantly lower (61%) in the denervated group, none of the measured variables in the resting fish was affected by the denervation. When swimming at  $U_{\text{crit}}$ , there were in both groups significant decreases in mixed venous pH,  $P_{\text{O}_2}$  and  $C_{\text{O}_2}$  and significant increases in heart rate, mean ventral aortic blood pressure, haematocrit, and concentrations of plasma lactate and plasma catecholamines. The values of most of these variables at  $U_{\text{crit}}$  were similar for both the groups. However, plasma lactate concentration at  $U_{\text{crit}}$  was significantly lower (50%) in the denervated group, although it increased to three times the resting value in this group of fish compared with an increase to 2.3 times the resting value in the sham-operated group.

There were substantially larger differences between the two groups in the levels of plasma catecholamines at  $U_{\text{crit}}$  (Fig. 1). Plasma adrenaline concentration in the sham-operated fish at  $U_{\text{crit}}$  was 6.7 times greater than that in the denervated fish. It rose to 11.5 times the resting value in sham-operated fish and to 4.3 times the resting value in the denervated group. Plasma noradrenaline concentration at  $U_{\text{crit}}$  was 4.6 times higher in the sham-operated fish than in the denervated group. It increased to 5.2 times the resting value in the former and to two times the resting value in the latter.

The fish in the two groups were of similar mass and length, and before any operative procedure  $U_{\text{crit}}$  was similar, at 1.1 body length s<sup>-1</sup>, in both groups. There were significant reductions in  $U_{\text{crit}}$  in sham-operated and denervated fish indicating that the surgical procedures themselves, as well as sectioning the first four pairs of spinal nerves, caused a reduction in swimming performance. Although  $U_{\text{crit}}$  after the operative procedures was not significantly different

In nine fish the first four pairs of spinal nerves were sectioned to denervate the head kidney (denervated fish) and in eight fish the nerves were identified but not sectioned (sham-operated fish).

\* Indicates a mean value significantly different from that for the same variable at rest within the same group.

† Indicates a mean value significantly different from that for the same variable in the sham-operated group.

between the two groups when using a two-tailed test, it was with a one-tailed test, and the ratio between  $U_{crit}$  after and  $U_{crit}$  before the operation was significantly lower in the denervated group of fish (when using a two-tailed test).

The effect of infusing saline or catecholamines into denervated fish upon  $U_{crit}$  and the variables measured at that time are given in Table 2. There are no significant differences in any of the resting values before the two bouts of swimming (i.e. with either saline or catecholamine infusion). Compared with the denervated fish in the initial series of experiments, resting values of haematocrit and plasma lactate concentration were higher and noradrenaline concentration was lower. As with the initial series of experiments, there were significant reductions at  $U_{crit}$  in mixed venous pH and significant increases in heart rate, mean ventral aortic blood pressure, and levels of plasma lactate and plasma catechol-

Fig. 1. Levels of plasma adrenaline (open columns) and noradrenaline (filled columns) in Atlantic cod, *Gadus morhua*. In series 1 the head kidney of the fish was denervated in nine fish (denervated) whereas in eight animals the nerves were identified but not sectioned (sham). Data were obtained in fish at rest or when swimming at critical velocity,  $U_{crit}$  (exercise). In series 2 the head kidney was denervated in all (eight) fish which were infused with saline or catecholamines while swimming. When infusing with catecholamines the objective was to obtain plasma concentrations similar to those recorded in sham-operated fish swimming at  $U_{crit}$ . Values are means + S.E.

amines during both bouts of swimming. (Note that haematocrit did not increase at  $U_{crit}$  during either of the swimming bouts.) The concentrations of plasma lactate at  $U_{crit}$  were similar to that seen in denervated fish during the first series of experiments. During both bouts of swimming, plasma lactate level was approximately 1.5 times the resting value at  $U_{crit}$ . During saline infusion, both adrenaline and noradrenaline concentrations at  $U_{crit}$  were 2.1 times the resting values, whereas during catecholamine infusion they were, at  $U_{crit}$ , 38 times and 22 times the resting values, respectively (Fig. 1). The actual concentrations reached at  $U_{crit}$  during catecholamine infusions were similar to those recorded in sham-operated fish swimming at  $U_{crit}$  (see Table 1).

The mass and length of the fish used in this series were similar to those of the animals used in the initial series (cf. Tables 1 and 2).  $U_{crit}$  in the denervated fish

Table 2. *The effects of infusing either saline or a mixture of the catecholamines adrenaline and noradrenaline (for details see text) on a number of physiological variables and critical swimming velocity ( $U_{crit}$ ) in eight Atlantic cod, *Gadus morhua*, in which the first four pairs of spinal nerves were sectioned to denervate the head kidney*

infused with saline (Table 2) was similar to that in the denervated fish without infusion (Table 1).

The swimming performance (i.e.  $U_{crit}$ ) of the former group of fish was slightly (8%) but significantly greater when they were infused with catecholamines than when they were infused with saline.

### Discussion

The observation that denervating the head kidney of cod significantly reduced the concentrations of plasma adrenaline and noradrenaline at  $U_{crit}$  and also significantly reduced the fishes' swimming performance, could well be interpreted as demonstrating the positive influence of circulating catecholamines on their swimming ability. However, the denervation is not selective. Sympathetic nerves to the heart and gills, as well as those to the head kidney, are sectioned as are the motor fibres to some anterior somatic muscles, including those to the pectoral fins. Thus, the reduced swimming performance could have resulted, at least in part, from the denervation of these other organs. The observation that infusion of

catecholamines in denervated fish significantly increased their  $U_{crit}$ , indicates that these hormones enhance the swimming performance of these animals. The data only indicate a marginal improvement, but in a number of the fish there was a noticeable improvement in the 'style' of swimming. Instead of the frequency of falling back to the grid increasing with time, it actually decreased for a short while after commencement of the highest rate of infusion of the catecholamines.

Of course, we have no idea which of the many possible mechanisms are the most important. Adrenergic vasomotor fibres, and not circulating catecholamines, are thought to be important in elevating blood pressure during exercise in cod (Axelsson & Nilsson, 1986). This proposal is supported by the present observation that the rise in ventral aortic pressure during swimming persists after denervation of the head kidney. Release from nerve terminals could also explain the significant rise in plasma catecholamine levels in swimming fish after denervation of the head kidney. Also, the rise in cardiac output during exercise in the cod is not impaired by total removal of autonomic influences (Axelsson, 1988). Unfortunately, it was not possible to obtain arterial blood samples, so we have no data on oxygenation of the arterial blood in denervated fish, and we did not measure intracellular pH (pHi) of the red blood corpuscles (RBCs). An interesting observation, which warrants further study, was that if the levels of plasma catecholamines were abnormally high at moderate swimming velocities, swimming was inhibited. In view of the findings of Smith *et al.* (1985) and Axelsson & Nilsson (1986), this inhibition is not likely to result from vasoconstriction in the locomotory muscles.

It is known that both adrenaline and noradrenaline cause vasodilatation in the branchial vasculature of cod, with adrenaline being the more potent (Wahlqvist, 1980). This  $\beta$ -adrenoceptor dilatation of afferent lamellar arterioles is probably mediated entirely by circulating catecholamines (Nilsson & Pettersson, 1981) which, together with  $\alpha$ -adrenoceptor constriction of efferent lamellar arterioles, may enhance oxygen transfer across the gills (Pettersson, 1983). Pettersson (1983) concluded that  $\alpha$ -adrenoceptor stimulation is the more potent in this respect, and it can be selectively mediated by the nervous system (Nilsson & Pettersson, 1981). The denervation procedure used in the present study would, therefore, have eliminated this effect.

There is evidence to suggest that the ability of rainbow trout and salmon to perform aerobic exercise after burst (anaerobic) swimming is not compromised because the elevated plasma catecholamine levels produced during the burst swimming serve to maintain pHi of the RBCs in the face of plasma acidosis (Primmatt *et al.* 1986; Randall *et al.* 1987). As there are increases in both plasma catecholamine levels and plasma acidosis in cod swimming at  $U_{crit}$ , this phenomenon could be an important component of the overall effect of circulating catecholamines on swimming performance in this fish.

PJB was in receipt of travel grants from The Royal Society and The Society for Endocrinology.
