SUMMARY

The food a honey bee female larva receives determines whether she develops into a large long-lived fertile queen or a short-lived sterile worker. Through wellestablished nutrient sensing and growth promoting functions in metazoans, the insulin/insulin-like growth factor 1 signaling (IIS) pathway has become a focal topic in investigations on how differences in food environment can be translated into internal signals responsible for queen-worker determination. However, low expression levels of two insulin receptors (AmInRs) in honey bee larvae and the failure of one AmInR to influence caste differentiation are in potential conflict with such a classical growth promoting role of IIS in queen-worker development. In view of such an apparent contradiction, and the fact that binding partners and affinities of these two AmInRs have not been worked out, we performed a functional study on insulin-like peptide genes (AmILP1 and AmILP2) in honey bee larvae by using a double-stranded RNA (dsRNA)mediated gene knockdown approach. We found that juvenile hormone (JH) levels were diminished by AmILP1 dsRNA treatment, while the AmILP2 knockdown caused a reduction in ovary size. Blood sugar titers were not significantly affected by the treatments. From these results we conclude that AmILP2 transcript levels may influence specific organ development, such as the ovary and body mass, while more general traits of caste differentiation, such as mandibles, may require additional regulators. In addition, JH production may be regulated by *AmILP1* expressed locally in the brain, similar to the function of certain *ILPs* in *Drosophila*.

INTRODUCTION

Eusocial insects, including honey bees, exhibit an environmentally-induced caste polyphenism that promotes colony efficiency through a morphology-based division of labor: while queens are functional egg-laying machines, workers forgo reproduction and, instead, care for the brood, defend the colony and forage for food (Hölldobler and Wilson, 2008). The ecological and evolutionary success of social insects (Hölldobler and Wilson, 2008) is largely built upon such division of labor, but the mechanisms that generate alternative phenotypes (castes) in Hymenoptera and termites are not fully understood (Hartfelder and Emlen, 2012).

The most considerable progress in understanding caste development has been made in the honey bee, Apis mellifera, where the primary trigger is differential feeding of the larvae. Queen larvae receive copious amounts of royal jelly, a glandular secretion produced by young worker bees, throughout all five larval instars (Haydak, 1970; Winston, 1987). In contrast, worker larvae are fed less frequently and receive a diet less rich in sugar (4% as compared to 12% in royal jelly) during the third and fourth larval instars (Asencot and Lensky, 1985). These diets induce a series of endogenous responses that result in differential phenotypes. The most studied endocrine regulator of caste differentiation is juvenile hormone (JH) (Rachinsky et al., 1990b; Rembold, 1987), which shows higher titers during the fourth to fifth instar in queen-destined larvae (Rachinsky and Hartfelder, 1990a; Rachinsky et al., 1990b). Functionally, JH application induces queen-like traits in larvae with restricted diet (Goewie, 1977; Rembold et al., 1974). Although the mode of action of JH in driving queen development is still rather unclear, its effect on ovary size (i.e. ovariole number), which is one of key morphological traits differing between gueens and workers, has been well revealed. JH affects ovary differentiation from the third larval instar until the onset of metamorphosis: high JH titers in queen larvae prevent autophagic programmed cell death (PCD) in the ovary (Schmidt Capella and Hartfelder, 2002), thus sustaining tissue survival and differentiation into the

large queen ovaries, whereas low JH titers in worker larvae cannot inhibit PCD, which removes 95-99% of the ovariole primordia and leads to the small worker-type ovaries.

Ovary size defines the reproductive status of queens and workers (Winston, 1987), and regulates worker social behaviors (Wang et al., 2009; Wang et al., 2010). The adult honey bee queen has up to 150 ovarioles in each of her ovaries and is only responsible for laying eggs. In contrast, workers, which are functionally sterile, typically only have on average 2-12 ovarioles per ovary (Blom et al., 1994; Michener, 2000; Winston, 1987). However, the ovariole numbers may vary, and *in vitro* rearing experiments showed that there is a morphospace gradient in which ovary phenotypes of the queen and worker are the extremes (Leimar et al., 2012; Linksvayer et al., 2011). In addition, ovary size is also correlated with foraging behavior in workers: workers with more ovarioles perform less retinue behavior (unpublished data, Galbraith, Wang, Amdam, Page and Grozinger), initiate foraging tasks earlier in life (Wang et al., 2009; Wang et al., 2010), prefer to collect pollen over nectar, and are more sensitive to sucrose than workers with fewer ovarioles (Amdam et al., 2006; Wang et al., 2009).

The release of the honey bee genome sequence (The Honey Bee Genome Sequencing Consortium, 2006), greatly facilitated investigations on how the nutrient stimuli are translated into endogenous molecular signals in honey bee caste differentiation. The focus has been set on two conserved eukaryotic nutrient-sensing pathways: the insulin/insulin like growth factor 1 signaling (IIS) pathway (Mutti et al., 2011a; Wolschin et al., 2011) and the closely related and interacting target-ofrapamycin (TOR) pathway (Patel et al., 2007). Larvae subjected to RNA interference (RNAi)-mediated gene knockdown of the insulin receptor substrate (IRS) and TOR consistently developed into workers even when receiving a queen diet (Kamakura, 2011; Mutti et al., 2011a; Patel et al., 2007). Since RNAi primarily targets the fat body (Jarosch and Moritz, 2011), a tissue functionally homologous to white adipose tissue and the liver in mammals (Chapman, 1998), these studies also provided evidence that IRS and TOR genes expressed in the fat body may remotely control JH production by the corpora allata (CA) in the retrocerebral complex (Mutti et al., 2011a). In addition, gene expression studies have revealed that the genes encoding two insulin-like peptides (AmILP1 and AmILP2) and two insulin receptors (AmInR1 and AmInR2) are

differentially expressed between queen and worker larvae (de Azevedo and Hartfelder, 2008; Wheeler et al., 2006). Together with the results of a recent study showing that epidermal growth factor receptor (*EGFR*) gene knockdown induces the worker phenotype (Kamakura, 2011), the current evidence indicates that caste development in honey bees involves a complex interaction network composed of the IIS/TOR/EGFR pathways, JH and ecdysteroids, which are classic developmental and reproductive hormones in *Drosophila* (Mirth and Riddiford, 2007) and other insect species (Chapman, 1998).

Nonetheless, upon a closer look, the regulatory network of honey bee caste development is not straightforward, especially for the IIS pathway. For instance, the expression levels of *AmInR1* and *AmInR2* in fourth-instar queen larvae decline to very low levels, just as the larvae show the highest growth rates (de Azevedo and Hartfelder, 2008). Furthermore, silencing one of *AmInR* genes did not affect caste fate in honey bees (Kamakura, 2011), suggesting the effect of IRS on queen-worker phenotype differentiation may be mediated by EGF receptors (EGFR), not through IIS (Mutti et al., 2011a).

Clearly, based on sequence similarity, *AmInR1* and *AmInR2* are putative genes for receptors of insulin-like peptides, the upstream signaling factors in IIS. However, their binding partners and respective binding affinities have not been investigated. The honey bee *AmILP1* and *AmILP2* genes also have high sequence similarity to *Drosophila ILPs* (*DILPs*) whose roles in the IIS have been intensively revealed. Previous studies on *AmILP1* and *AmILP2* in honey bee brain and fat body suggested that the proteins encoded by *AmILP1* and *AmILP2* genes mediate nutritional signals (Ament et al., 2008; Ament et al., 2010) and regulate energy metabolisms (Wang et al., 2012), which are conserved functions of ILPs across species including *Drosophila*. Studies on *AmILP1* levels in the brain of honey bee workers (Ament et al., 2010; Corona et al., 2007) have shown that these are negatively correlated with individual nutritional status and positively related to JH titers (Ament et al., 2008). Additionally, low levels of *AmILP1* transcripts in the fat body of adult bees are linked to high blood sugar levels (Wang et al., 2012). In contrast, the regulation and function of AmILP2 is less understood since

AmILP2 expression does not consistently respond to the factors as AmILP1 does in adult honey bees (Amdam, 2010; Wheeler et al., 2006).

In *Drosophila*, silencing *DILPs* strongly affected larval development and carbohydrate metabolism (Brogiolo et al., 2001; Rulifson et al., 2002). Although gene expression profiles of *AmILPs* in honey bee larvae differ among the castes (de Azevedo and Hartfelder, 2008; Wheeler et al., 2006), actual functional data of *AmILP1* and *AmILP2* in larval development are still missing. Thus, to gain insights into *AmILP1* and *AmILP2* gene functions in queen-worker differentiation we used an RNAi-mediated gene knockdown approach in larvae reared in an *in vitro* system (Patel et al., 2007). The treated and control larvae were assayed for transcript levels of *AmILP1* and *AmILP2*, hemolymph sugar and JH levels, and larval body mass at the fifth larval instar, when developmental hormone titers (JH and ecdysteroids) are very different and when the caste-specific differentiation of the ovaries is in the most pronounced process. In addition, we screened the expression of caste phenotype characters of the adults that emerged from such treatments. The results are indicative of differential roles for the *AmILPs* in the queen-worker differentiation process.

MATERIALS AND METHODS

Experimental design

In this study, we used a full factorial design in which *AmILP1* RNAi and *AmILP2* RNAi treatments are the two independent factors. There were two levels for each of the factors: '0' (no RNAi) and '1' (RNAi). It is known that a factorial experimental design is 'more efficient than one-factor-at-a-time experiments and can detect interactions' (Montgomery, 1997). This allowed us to study the effect of each factor on the traits we are most interested in, as well as the effects of interactions between the two factors on those traits (Montgomery, 1997). Studies on ILPs in other insects have found that the functions of ILPs are usually linked (Wu and Brown, 2006). And it has been proposed that AmILP1 and AmILP2 acts as agonist and antagonist of their respective receptors, but no experimental evidence has been found so far (Nilsen et al., 2011). Therefore, determining the interaction between *AmILP1* and *amILP2* should be informative for

understanding how the functions of *AmILP1* and *AmILP2* are interconnected in honey bees.

dsRNA synthesis

DNA fragments of the *AmILP1* and *AmILP2* genes flanked on both sides with a T7 promoter sequence were inserted into the commercial T-easy vector (Promega, Madison, WI, USA) using the primers listed in Table S1. Plasmids were extracted and sequenced to validate the DNA sequences of *AmILP1* and *AmILP2*. Double-stranded RNAs (dsRNAs) of *AmILP1* and *AmILP2* were synthesized following a previously established protocol (Amdam et al., 2003). The gene sequence of the green fluorescent protein (GFP), which is not found in the honey bee genome, was used to produce a non-target dsRNA, serving as control dsRNA in the RNAi assays.

In vitro rearing of honey bee larvae

Wild-type honey bees maintained at the Honey Bee Research Facility at the Arizona State University Polytechnic campus in Mesa, AZ, were used in these experiments. Queens from three wild-type colonies were caged for 24 h and newly hatched larvae (12-18 h-old, n = 1000) were grafted into Petri dishes containing a previously established nutrient-rich diet suitable for in vitro rearing queens (Patel et al., 2007) and were kept in a cell culture incubator at 33 °C and 80% humidity (Patel et al., 2007). On the second day, larvae of similar size were grafted from the Petri dishes and randomly distributed into 24-well culture plates (6 larvae/ well). A full factorial design was applied on our dsRNA feeding regime, and AmILP1 dsRNA and AmILP2 dsRNA were used as two independent factors. Four experimental treatments were created: AmILP1 dsRNA, AmILP2 dsRNA, AmILP1+AmILP2 dsRNAs, and gfp dsRNA. Each well contained the larval diet supplemented with 200 µg/ml of each dsRNA respectively. Therefore the total dsRNA was 200 µg/ml for AmILP1 dsRNA, AmILP2 dsRNA and gfp dsRNA treatment groups, and 400 µg/ml for AmILP1 +AmILP2 dsRNA group. Using similar factorial designs in both honey bee larvae and adults, previous studies on gene knockdown have shown that the amount of dsRNA in combined treatment groups does not cause any unspecific or adverse effects (Mutti et al. 2011a; Wang et al., 2012). Every 12 hours, the larvae were transferred to new diets in new plates, with changes of the position on the plate in a randomized design to minimize any location effects. After two days of feeding on the dsRNA-containing diet and 1.5 days of feeding on dsRNA-free diet, 20 larvae from each treatment group were collected to validate the gene knockdown and to reveal larval physiology responding to the treatments. The remaining larvae continued to be fed with dsRNA-free diet until they began defecating. Subsequently they were transferred to filter paper-lined Petri dishes, with filter paper being changed every day as they passed the pupal stage, and finally emerged as adult bees in the Petri dishes.

Sampling of hemolymph and larval body for gene expression, blood sugar and JH level analyses

Larvae retrieved from the experimental setup were cleaned by carefully wiping with tissue paper, and were weighed on a digital scale (VWR, Gaithersburg, MD, USA). The body of the larvae was pierced with a 30G BD needle, so that two samples of extruding hemolymph could be collected from each larva with glass capillaries (VWR, Gaithersburg, MD, USA). These hemolymph samples were used to assay sugar levels and JH titers, respectively. The hemolymph samples for carbohydrate measurement were immediately frozen on dry ice and kept at -80 °C until use. The hemolymph samples for testing JH titers were collected into glass vials containing 500 µl hexane and stored at -20 °C until use. The remaining carcasses of the larvae were transferred into Eppendorf tubes containing 500 µl TRIzol reagent (Invitrogen, Carlsbad, USA), flash-frozen in liquid nitrogen and stored at -80 °C.

RNA extraction and cDNA synthesis

After thawing and homogenization in the TRIzol reagent, RNA was extracted following the manufacturer's instructions. The quality and quantity of RNA was determined by spectrophotometry (Nanovue, GE Healthcare). DNase (RNase-free, DNase kit, Applied Biosystems, Bedford. MA, USA) was added to the total RNA extract to remove trace DNA contaminants, and 1 µg of such treated RNA was used for reverse transcription following an established method (Wang et al., 2009) using TaqMan® Reverse Transcription Reagents (Applied Biosystems, Bedford. MA, USA).

Quantitative Real-time PCR analyses

First-strand cDNA was used for real-time quantitative PCR (RT-qPCR) assays. Before performing the RT-qPCR, PCR amplicons from each gene were sequenced to validate the specificity of the primers (Table S2). A dilution series of cDNA was used to establish standard curves for each gene, and amplification efficiencies were calculated based on an established method (Livak and Schmittgen, 2001; Pfaffl, 2001). After verifying that AmILP1, AmILP2 and Amrp49 primers had similar amplification efficiencies, 15 samples were randomly picked from each treatment group for expression analysis. Each biological sample was run in technical triplicates on an ABI Prism 7500 Real-Time PCR system (Applied Biosystems, Bedford, MA, USA) for measuring AmILP1 and AmILP2 transcript levels in comparison with those of the reference gene *Amrp49* by means of the Delta-Delta Ct method (Livak and Schmittgen, 2001). Studies have shown that *Amrp49*, which has been renamed as *rpl23* (AF441189) in the honey bee genome version Amel 4.5, is stably expressed during larval development (Lourenco et al., 2008; Reim et al. 2013) and in adults (Cameron et al. 2013). Therefore Amrp49 is commonly used as a reference gene during the larval stage (de Azevedo and Hartfelder 2008; Martins et al. 2010) and also the adult stage of honey bees (Ben-Shahar et al. 2003; Navajas et al., 2008). RT-qPCR conditions were used as described previously for these genes (de Azevedo and Hartfelder, 2008). By monitoring negative control samples (without reverse transcriptase) and melting curve analysis, we verified that the RT-qPCR assays were not confounded by DNA contamination or primer dimers (Vandesompele et al., 2002).

Glucose and trehalose measurements

Glucose levels in the hemolymph were analyzed using a Glucose (HK) Assay Kit (Sigma, Louis, MO, USA), following an established laboratory protocol (Hartfelder et al., 2013; Wang et al., 2012). After adding 1 ml of the glucose reagent to each hemolymph sample, these were incubated for 15 min at room temperature. A series of glucose dilutions (0, 0.5, 1, 5, 10, 30, 50 and 100 μ g/ml) was prepared to set up a standard curve. After the incubation, 100 μ l of each standard and sample solution were

transferred in triplicate to 96-microplates. Absorbance at 340 nm was measured using an xMarkTM Microplate Absorbance spectrophotometer (Bio-Rad, Hercules, CA, USA) and sample glucose concentrations were calculated by linear regression. After taking the glucose readings, 0.5 μ l of trehalase (Sigma, Louis, MO, USA) (0.05 units/ml) was added to each well. The second reading for both standards and samples was taken after an overnight incubation at 37 °C. Glucose produced from trehalose was calculated, first by subtraction of the first glucose concentration value from the second total glucose concentration, which was then entered into the equation: trehalose (μ g) = glucose (μ g) × 342.3/(180.2×2).

JH radioimmunoassay

JH extraction from the 1 µl hemolymph aliquots in hexane was done following a liquid-phase separation protocol established for honey bee hemolymph (Huang et al., 1994). After adding 1 ml of NaCl (0.9%) and 1 ml hexane, the mixture was vigorously vortexed and the phases were separated by centrifugation (700 x g). After retrieving the hexane phase, the extraction was repeated twice by adding 1 ml hexane each time. The pooled hexane phases were dried by vacuum centrifugation, and the residues were redissolved in 100 µl toluene containing 0.5% (v:v) 1,2 propanediol (Sigma, St. Louis, MO, USA) and transferred to 1.5 ml glass vials. Before starting the radioimmunoassay, the solvent was removed by vacuum centrifugation.

A JH-specific antiserum (Goodman et al., 1990), previously validated for JH detection in bees (Amdam et al., 2007; Guidugli et al., 2005) was diluted 1:1250 in phosphate buffer supplemented with bovine serum albumin (0.1%) and rabbit immunoglobulin G (0.1%). The assays were performed with [10-3H(N)]-juvenile hormone III (spec. activity 19.4 Ci/mmol, Perkin Elmer, Boston, MA, USA) diluted in phosphate buffer to 6,000–6,500 cpm/100 μl. Juvenile hormone III (Fluka, Buchs, Switzerland) was used as nonradioactive ligand. Standard curves were set up to cover a 50 pg to 10 ng range.

The RIA was conducted following a procedure established by Goodman *et al.* (1990) and detailed for honey bees (Hartfelder et al., 2013). Samples were incubated overnight at 4°C, then supplemented with saturated ammonium sulfate (50% final conc.)

to separate antibody-bound from free JH by centrifugation at 7,500 x g for 15 min. After washing the pellets with 50% ammonium sulfate and a novel precipitation/centrifugation step, the pellets were redissolved in 80 μ I water before adding 5 ml of liquid scintillation cocktail (Optiphase Hisafe3, Perkin Elmer, Boston, MA, USA). Standard curve values were entered into a four-parameter fitting Excel spreadsheet specifically designed for enzyme-linked immunoassays (EIA) and radioimmunoassay (RIA) analyses (Bachem, Bubendorf, Switzerland; available from https://www.bachem.com/service-support/immunoassay-calculator/), based on the equation $y=((a-d)/(1+(x/c)^b))+d$, where a=maximum, b=slope, c=IC50, and d=minimum. Sample JH concentrations obtained by this polynomial regression were expressed as JH-III equivalents (pg/ μ I hemolymph).

Scoring ovariole number and additional morphological characters

Mandible and sting form, presence of a corbicula (pollen basket) and spermatheca, and ovary size of the emerged adults were assessed under a dissecting Leica MA12 microscope (Leica, Wetzlar, Germany). Bees with more than 70 ovarioles, notched mandibles, a smooth stinger, a spermatheca and lacking a corbicula were classified as queens (Mutti et al., 2011b). Alternatively, workers were considered to have less than 20 ovarioles, a barbed stinger and a corbicula (Mutti et al., 2011b). Intermediates were those with 20 to 70 ovarioles and a mixed set of the other characters (Mutti et al., 2011b).

Statistical analysis

Gene expression data were log transformed to approximate normality (Wang et al., 2009), as verified by Bartlett and Levene's homogeneity test. A factorial ANOVA was used to test the effect of *AmILP1* and *AmILP2* dsRNAs on gene expression, followed by Fisher Fisher least significant difference (LSD) tests in *post-hoc* comparisons. A Pearson Correlation Assay was used to reveal whether larval weight was correlated with *AmILP1* and *AmILP2* transcript levels and with JH titers. The factorial ANOVA was also used to test whether the treatment affected each morphological character such as ovariole number, mandible, stinger, corbicula or

spermatheca. A principle component analysis (PCA) was applied on these multiple morphological characters to clarify general distribution patterns and separations of the bees from different treatment groups by reducing dimensions of variables. Then, a Kruskal-Wallis ANOVA was used to analyze the treatment effect on the values of sample bees given by the first principle component (PC1). These analyses were performed using STATISTICA 10.0 (StatSoft) software.

RESULTS

Quantitative validation of AmILP1 and AmILP2 knockdown in a full factorial experimental design

The individual whole-body RNA extracts from fifth-instar larvae were assayed using an RT-qPCR protocol for AmILP1 and AmILP2 gene-knockdown verification (n =15). The overall effect of the factors (AmILP1 dsRNA treatment and AmILP2 dsRNA treatment) was determined by the main effect of a factorial ANOVA analysis. AmILP1 transcript levels were unaffected by either AmILP1 or AmILP2 dsRNAs treatments (Factorial ANOVA, n = 15, main effect of AmILP1 dsRNA: $F_{(1,56)} = 0.1392$, p = 0.6620; main effect of AmILP2 dsRNA: $F_{(1,56)} = 1.0447$, p = 0.3111) (Fig. 1 A and B). However, there was a significant decrease in AmILP2 transcript levels in larvae with AmILP2 dsRNA treatment (Factorial ANOVA, n = 15, main effect of AmILP2 dsRNA: F_(1, 56) = 20.9941, p < 0.0001) (Fig. 1 E), but not in those treated with AmILP1 dsRNA (Factorial ANOVA, n = 15, main effect of *AmILP1* dsRNA; $F_{(1,56)} = 1.5382$, p = 0.2201) (Fig. 1 D). Since the main effect of AmILP2 dsRNA on AmILP2 gene expression shown in Fig. 1 E includes the effect of AmILP2 dsRNA at two levels of AmILP1 dsRNA treatment (0 and 1), this result indicates that AmILP2 dsRNA, dependent or independent of AmILP1 dsRNA, significantly down-regulated the expression of its target gene at the whole-body level.

In order to determine whether or not AmILP1 dsRNA contributed to the main effect of AmILP2 dsRNA on AmILP2 expression, we looked at the interactions between AmILP1 dsRNA and AmILP2 dsRNA treatments. We found that there was no interaction between these two treatments on AmILP1 expression (Factorial ANOVA, interaction effect: $F_{(1, 56)} = 2.1251$, p = 0.1505, Fig. 1 C) but a significant interaction on AmILP2

gene expression (Factorial ANOVA, F_(1,56) = 41.5698, interaction effect: p < 0.0001, Fig. 1 F), suggesting that the reduction of *AmILP2* expression by *AmILP2* dsRNA (Fig. 1 E) was dependent on the level of *AmILP1* dsRNA treatment. Next, we performed a Fisher's least significant difference (LSD) *post-hoc* test to further dissect how the four treatment groups (*gfp*, *AmILP1* dsRNA, *AmILP2* dsRNA and *AmILp1* dsRNA+*AmILP2* dsRNA) contributed to the main effects of *AmILP2* dsRNA in this study. We found that, compared to *gfp* controls, (i) single *AmILP1* dsRNA treatment actually increased *AmILP2* transcript level (p<0.0001, Fig. 1 F), (ii) single *AmILP2* dsRNA treatment, on its own, did not significantly reduce *AmILP2* mRNA levels (p = 0.1985), but (iii) the combined *AmILP1* dsRNA and *AmILP2* dsRNA significantly decreased *AmILP2* transcript abundance (p = 0.0405). These results suggest that the level of *AmILP1* dsRNA treatment contributed to the significant main effect of *AmILP2* dsRNA in a whole larva (Fig. 1 E): the application of *AmILP2* dsRNA alone did not cause a reduction in the *AmILP2* mRNA level, but *AmILP1* dsRNA application enhanced the effect of *AmILP2* dsRNA– resulting in a significant decrease in *AmILP2* transcript abundance in Fig. 1 E.

Glucose and trehalose titers in the hemolymph

Studies in *Drosophila* indicated that *ILPs* in the brain were involved in regulating carbohydrate metabolism and blood sugar titers (Broughton et al., 2005; Saltiel and Kahn, 2001), and we previously found that *AmILP1* gene expression in adult honey bees was linked with blood sugar levels (Wang et al., 2012). Here, we measured carbohydrate reserves (glucose and trehalose) in the hemolymph in order to test whether the *AmILPs* may directly regulate blood sugar titers during honey bee larval development. We found that neither glucose nor trehalose concentrations were influenced by either *AmILP1* dsRNA or *AmILP2* dsRNA treatment (Factorial ANOVA, main effect of *AmILP1* dsRNA: n = 20, $F_{(1, 76) \text{ glucose}} = 0.1310$, p = 0.7184 and $F_{(1, 76) \text{ glucose}} = 0.11530$, p = 0.6968; main effect of *AmILP2* dsRNA: $F_{(1, 76) \text{ glucose}} = 0.8100$, p = 0.1825 and $F_{(1, 76) \text{ trehalose}} = 0.7659$, p = 0.3843) (Fig. 2 A, B, D, E). There was also no interaction between *AmILP1* dsRNA and *AmILP2* dsRNA treatments with either sugar contents (Factorial ANOVA, $F_{(1, 76) \text{ glucose}} = 0.9799$, p = 0.3254; $F_{(1, 76) \text{ trehalose}} = 0.1190$, p = 0.7311) (Fig. 2C, F). Considering that only *AmILP2* knockdown was

validated statistically at the whole-body RNA levels in larvae, we infer that *AmILP*2 does not directly regulate hemolymph carbohydrate reserves in honey bee larvae.

Hemolymph JH titers in AmILP1 and AmILP2 dsRNAs treated larvae

JH is a central regulator controlling queen caste development, and its levels can be regulated by EGF signaling (Kamakura, 2011) and affected by both IRS and TOR knockdowns (Jin and Esteva, 2008; Mutti et al., 2011a). Therefore, examining whether JH is affected by the AmILP knockdowns is a key to understanding the relationship between JH and IIS in honey bee larvae. Upon measuring the JH titers in larval hemolymph by means of a specific radioimmunoassay, we found that the JH titers were significantly decreased by AmILP1 dsRNA (Factorial ANOVA, n = 16-19, $F_{(1, 67)} =$ 5.0970, p = 0.0272) (Fig. 3 A), but not by AmILP2 RNAi (Factorial ANOVA, n = 16-19, $F_{(1, 67)} = 1.7474$, p = 0.1907) (Fig. 3 B). There was no significant interaction effect between AmILP1 and AmILP2 dsRNA treatments (Factorial ANOVA, $F_{(1,76)} = 1.4309$, p = 0.2358) (Fig. 3 C), indicating the effect of AmILP1 dsRNA on JH was independent of AmILP2 dsRNA. Post-hoc analysis further showed that the larvae treated with AmILP1 dsRNA (Fisher LSD: P = 0.0114) and the larvae treated with combined AmILP1 and AmILP2 dsRNA (Fisher LSD: P = 0.0135) had lower JH levels compared to gfp controls (Fig. 3 C). Since we could not verify a knockdown in terms of AmILP1 transcript level in the same individual larva, these results raised an interesting question about whether the change in JH titers in the bees treated with AmILP1 dsRNA was specific. It is, however, plausible that the whole-body RNA levels measured may have masked changes in AmILP1 transcript levels that only occurred in a small subset of cells, such as in the neuroendocrine axis.

Body mass

There is a correlation between body mass and ovariole number in honey bees (Linksvayer et al., 2011; Snodgrass, 1956), but a recent *in vitro* rearing study has shown that body size can be independent of ovariole number and other queen phenotype characters (Linksvayer et al., 2011), inferring that caste morphological traits may be regulated by separated pathways (Kamakura, 2011). In our study, the body mass of

fifth-instar larvae was not affected by either AmILP1 dsRNA or AmILP2 dsRNA (Factorial ANOVA, n = 20, main effect of AmILP1 dsRNA: $F_{(1, 76)} = 1.3834$, p = 0.2432; main effect of AmILP2 dsRNA, $F_{(1, 76)} = 1.6561$, p = 0.2020). (Fig. 4 A and B), but there was a significant interaction effect between AmILP1 and AmILP2 dsRNAs (Factorial ANOVA, $F_{(1, 76)} = 5.5990$, p = 0.0205) (Fig. 4 C). These results suggest that the effect of AmILP1 dsRNA on the body mass of the fifth-instar larvae depends on the level of AmILP2 dsRNA: AmILP1 dsRNA increased the body mass in the absence of AmILP2 dsRNA, but combined AmILP1 dsRNA and AmILP2 dsRNA tended to reduce body mass. Post-hoc analysis further showed that the larvae treated with AmILP1 dsRNA were heavier than gfp control larvae (post-hoc LSD: P = 0.0010) and the larvae treated with AmILP1 and AmILP2 dsRNAs (post-hoc LSD: P = 0.0465).

Since AmILPs and JH are thought to be interconnected in the regulation of honey bee caste development, we also plotted the respective larval weight against AmILP1 and AmILP2 expression and JH titers to explore putative associations. For both AmILP1 and AmILP2, we found significant positive correlations with larval weight (Pearson correlation, n= 57, AmILP1: p= 0.0250; AmILP2: p = 0.0092) (Fig. 5 A, B), suggesting that both AmILPs are involved in regulating larval development either in a direct or indirect way, this supporting a hypothesis for general functions of AmILP1 and AmILP2 in honey bee development. In contrast, JH titers were negatively correlated with larval weight (Pearson correlation, n = 57, p = 0.0004) (Fig. 5 C). This negative correlation seems contradictory to the general role of JH in honey bee caste differentiation. However, the fifth instar is a critical stage to initiate honey bee metamorphosis, coordinated in concert by JH and ecdysteroid titers. Perhaps such dynamic changes (temporal or rapid) resulted in the negative relationship between JH and body mass. Nonetheless, further investigation is needed to test this hypothesis.

Ovariole number and other morphological traits

Ovaries were dissected and ovariole number was counted after adult eclosion. We found that ovariole number was significantly reduced in bees subject to AmILP2 RNAi (Factorial ANOVA, n = 12-27, $F_{(1, 67)} = 5.2069$, p = 0.0257) (Fig. 6 B), but not to AmILP1 dsRNA (Factorial ANOVA, n = 12-27, $F_{(1, 67)} = 1.1859$, p = 0.2801 (Fig. 6 A).

 There was no interaction between AmILP1 and AmILP2 dsRNA treatments (Factorial ANOVA, $F_{(1, 67)} = 0.0642$, p = 0.8008) (Fig. 6 C), suggesting AmILP2 dsRNA reduced the ovariole number independent of AmILP1 dsRNA. Post-hoc analysis showed that the bees treated with AmILP2 dsRNA (Fisher LSD: p = 0.0067) and the bees treated with a combination of AmILP1 and AmILP2 dsRNA (Fisher LSD: p = 0.0570) had significantly fewer ovarioles than the bees treated with AmILP1 dsRNA alone.

Other morphological characters, such as mandible shape, stinger shape, size of spermatheca and presence/absence of a corbicula were also monitored based on an established protocol (Mutti et al., 2011b; Patel et al., 2007). There was no main effect of either *AmILP1* dsRNA or *AmILP2* dsRNA, and no interaction effect on any of these morphological characters (Factorial ANOVA, p>0.05; detailed results can be found in Table S3).

A principal component analysis was utilized to clarify general patterns, similarities or separations of cases between the different treatment groups by reducing the dimensions of morphological variables. This revealed that 73.25% of the total variation can be explained by the first principle component (PC1), and 9.61% of the remaining total variation can be explained by the second principle component (PC2). The eigenvalue of PC1 was 3.6623, and other PCs did not exceed 1 (Table S4), meaning that PC1 contributed more to the variance than the original variables, but other PCs could be considered as sampling noise. All the variables (morphological characters) contributed almost equally to PC1 (contributions: 17% - 22%, Table S5). Analysis of PC1 vs. PC2 (Fig. 7) revealed that along PC1 there was no clear separation among cases (bees) according to treatments. Next, we carried out a Kruskal-Wallis ANOVA to test whether the distributions of samples in treatment groups in PC1 were different. There was no difference in the distributions of samples among the treatment groups in PC1 (the combined variable) (Kruskal-Wallis ANOVA: Chi-Square = 4.7526, p = 0.1908), suggesting that the treatments did not significantly influence gueen-worker caste differentiation, which is characterized by these multiple morphological characters, though *AmILP*2 RNAi significantly affected ovariole number.

DISCUSSION

By using a gene knockdown approach, we herein performed the first functional study to investigate the role of insulin peptide encoding genes, *AmILP1* and *AmILP2*, in queen-worker differentiation during honey bee larval development. Our data show that *AmILP2* expression was susceptible to *AmILP2* RNAi when *AmILP1* dsRNA was used simultaneously, which resulted in diminished transcript levels in the whole larval body. Although *AmILP2* dsRNA did not cause any change in hemolymph JH levels, it had an effect on ovariole number of adult bees. In contrast, *AmILP1* expression at the whole-body level was not affected by *AmILP1* dsRNA treatment, but the hemolymph JH levels in these larvae were significantly reduced by the treatment. Thus, a general conclusion that can be drawn from these results is that *AmILP1* and *AmILP2* dsRNAs have differential efficacies to down-regulate the target genes in the whole larval body.

Efficacies of AmILP1 and AmILP2 RNAi in the fat body

RNAi efficacy is affected by many factors, such as the specificity of the dsRNA, RNAi delivery method, the expression level of the gene, cell types in the target tissue and the nature of regulatory machinery of RNAi. In honey bees, both AmILP-encoding genes are represented by a single copy each in the honey bee genome (de Azevedo and Hartfelder, 2008). Their transcripts are relatively short (around 400 bp), and there is no evidence for transcript variants. Additionally, the dsRNAs were designed to target 260-280 bp regions of *AmILP1* and *AmILP2*, and no off-target matches were found by alignments against the honey bee genome. Furthermore, the final concentrations of dsRNA (200 µg/ml) in the larval diet and the *in vitro* rearing protocol have been validated in previous *TOR* and *IRS* knockdown studies (Mutti et al., 2011b; Patel et al., 2007). In this study, we achieved an overall 30% reduction in *AmILP2* transcript levels by *AmILP2* RNAi. Therefore it is unlikely that dsRNA specificity and the protocol have issues resulting in the differential efficacies between *AmILP1* and *AmILP2* RNAi.

A factor that may explain why we did not achieve a significant *AmILP1* gene knockdown could be the low level of *AmILP1* expression in early fifth-instar larvae (de Azevedo and Hartfelder, 2008). So, the difficulty encountered in achieving *AmILP1* knockdown could be related to the general difficulty in down-regulating a gene with low transcript abundance. Additionally, differential cell-type specificities between *AmILPs*

expression and dsRNA targeting may be another reason for the differential RNAi efficacies. In adult honey bees, the tissue that best responds to a dsRNA treatment is the fat body, (Amdam et al., 2003; Jarosch and Moritz, 2011), and it is also the predominant tissue type in larvae. The insect fat body is composed of two cell types, trophocytes and oenocytes. A recent study has revealed that the expression of *AmILP1* and *AmILP2* in honey bee fat body has different cell specificities: *AmILP1* is highly expressed in oenocytes and *AmILP2* is so in both oenocytes and trophocytes (Nilsen et al., 2011). However, the preferential uptake characteristics of dsRNA molecules by oenocytes and trophocytes are different, with trophocytes uptaking considerably more dsRNA than oenocytes (Jarosch and Moritz, 2011). Therefore, the lack of a significant *AmILP1* knockdown in our experiments may be due to the poor *AmILP1* dsRNA uptake capability of oenocytes (Jarosch and Moritz, 2011), as well as the low transcript abundance of *AmILP1* in the developmental stage. Since gene knockdown is dosedependent, increasing the dosage or extending dsRNA feeding time may be able to raise the success rate for knocking down *AmILP1* gene in the fat body in future studies.

In this study, the AmILP2 gene was not directly knocked down when its dsRNA was applied only. One of the reasons could again be a low level of AmILP2 expression in fifth-instar larvae (de Azevedo and Hartfelder, 2008). However, we found that AmILP2 dsRNA significantly down-regulated AmILP2 gene expression when AmILP1 dsRNA was applied simultaneously, whereas AmILP1 dsRNA treatment caused an increase in Am/LP2 mRNA. Though there is no simple explanation for this phenomenon, it is worthy of note that the effect of RNAi can be physically amplified and systemically spread in some organisms including Caenorhabditis elegans and certain insects (Tomoyasu et al., 2008; Miller et al., 2012). These processes involve RNA-directed RNA polymerase (RdRP) activity, which depends on high levels of expression of target RNA (Dougherty and Parks, 1995; Sijen et al., 2001). Therefore, the potency of AmILP2 dsRNA might have been enhanced once the AmILP2 transcript level was increased by AmILP1 dsRNA. As the RNAi machinery includes both transcriptional and post transcriptional gene silencing modes (Noma et al., 2004), this can involve complex negative and positive feedbacks (Xie et al., 2003; Grewal and Elgin, 2007). In addition, regulatory mechanisms in RNAi vary among organisms (Tomoyasu et al., 2008), and in insects

how RNAi is controlled and regulated is still poorly understood. Therefore, future studies directed towards detecting and identifying regulatory mechanisms of RNAi in insects are likely to shed light on the question how *AmILP1* dsRNA could enhance the effect of *AmILP2* dsRNA.

Potential relationship of brain AmILP1 to JH production and AmILP2

Interestingly, we observed a significant reduction of JH in response to AmILP1 dsRNA treatment, even though no significant down-regulation was achieved for this gene at the whole body level. It is worthy of note that the majority of ILPs are produced in the brain of most insect species (Antonova et al., 2012; Brogiolo et al., 2001; Iga and Smagghe, 2011; Riehle et al., 2006), including honey bees (Ament et al., 2008; Corona et al., 2007) and Drosophila (Brogiolo et al., 2001). And JH is synthesized in the closely associated corpora allata (CA) of the insect retrocerebral complex (Goodman and Cusson, 2012), as also shown for honey bee larvae (Rachinsky and Hartfelder, 1990a). In Drosophila, the small cluster of AmILP-producing neuroendocrine cells was shown to transmit ILPs to the JH producing CA (Krieger et al., 2004) by axons directly projecting to the ring gland (Cao and Brown, 2001; Géminard et al., 2006). In line with these findings (Lane and Swales, 1978; Restifo et al., 1995) we hypothesize that a cluster of AmILP-producing cells in the brain of honey bee larvae may have been targeted by AmILP1 dsRNA, which consequently affected JH production in the CA. Although the adult honey bee brain has been shown to be resilient to a dsRNA treatment (Farooqui et al., 2004; Jarosch and Moritz, 2011), it is possible that the larval hemolymph-brain barrier could be more leaky than that of adults (Lane and Swales, 1978; Restifo et al., 1995), especially during the onset of metamorphosis.

Furthermore, several studies have provided evidence for a positive regulation of *ILP* expression by JH in many insect species including *Drosophila* (Corona et al., 2007; Sheng et al., 2011; Tu et al., 2005). Reciprocally, it was found that JH synthesis was modulated by brain *Drosophila* ILPs (Tatar et al., 2003). In honey bees, the treatment with methoprene (a JH analogue) positively affected brain *AmILP1* levels in both adult queens and workers (Corona et al., 2007). Our recent study also suggested that *AmILP1* expression in the fat body is negatively linked to the hemolymph JH titers in

adult worker bees (Wang et al., 2012). In addition, a connection between *AmILP1* expression and JH synthesis was proposed based on the temporal coincidence between the peaks of *AmILP1* expression and JH titers in honey bee larvae (Wheeler et al., 2006). Finally, interference with downstream regulators of IIS and/or EGF signaling, such as the *IRS* (Mutti et al., 2011b) and *TOR* genes (Patel et al., 2007), resulted in a decrease in JH titers (Mutti et al., 2011a). Taken together, the reduction in JH levels seen as a result of *AmILP1* dsRNA treatment is likely a specific effect of *AmILP1* RNAi, and our study provides first evidence that brain *AmILP1* may regulate JH production in honey bee larvae.

Finally, our study indicates that the expression of brain AmILP1 and fat-body AmILP2 are correlated in honey bees. In Drosophila, over-expression of insulin-like peptides (DILPs) in the fat body inhibited brain DILP secretions (Bai et al., 2012), and gene knockouts of DILPs in the brain caused synergy and compensation of expression of DILPs in the fat body (Gronke et al., 2010). In honey bees, previous studies have suggested that AmILP1 and AmILP2 act as an agonist and an antagonist, respectively, of InRs in the brain regulating JH secretion (Nilsen et al., 2011). However, how brain AmILPs connect with fat-body AmILPs is poorly understood. Here, we found that AmILP1 dsRNA was able to increase AmILP2 transcript abundance in the whole body of fifth-instar larvae (Fig. 1F), with fat body making the major tissue contribution. Since AmILP1 dsRNA probably affects the brain AmILP1 secretion in fifth-instar larvae, our findings suggest that fat body AmILP2 compensates the down-regulation of brain AmILP1, thus representing a circuitry similar to that found in Drosophila. Although AmILP1 dsRNA also induced a decrease in JH titers, we did not find any correlation between JH and fat-body AmILP2 levels in these fifth-instar larvae (Fig. S1), suggesting that JH is not involved in this hypothetical compensatory response of fat-body *AmILP2*.

Roles of JH and AmILP2 in worker caste development

Experimental and modeling evidence supports that an elevated JH titer during the fourth and early fifth instar of honey bees inhibits the induction of autophagic cell death in the larval ovary (Schmidt Capella and Hartfelder, 2002), and rescues the queen phenotype after *IRS* and/or *TOR* gene knockdowns (Mutti et al., 2011a). Therefore, a

logical conclusion would be that decreasing JH levels would promote ovary degradation and induce the worker phenotype. In our study, however, the main effect of *AmILP1* dsRNA caused an approximately 40% reduction in JH titers, but had no apparent effects on ovary degradation and caste characters in general, suggesting that other regulators in addition to a low JH titer may be required for full worker phenotype development. This is supported by the finding that the down-regulation of *AmILP2* transcript abundance in the fat body, in addition to an approximately 35%, though statistically not significant, reduction in JH titers in these larvae was associated with fewer ovarioles. Together with the fact that down-regulation of *IRS* and *TOR* in the larval fat body reduces JH, this suggests that the fat body secretes regulators which modulate CA activity.

Moreover, our results indicate that *AmILP1* and *AmILP2* have different roles during honey bee larval development, which is also consistent with their expression profiles (de Azevedo and Hartfelder, 2008). In *Drosophila*, different ILPs show tissue-specific functions. Whereas brain ILPs tend to regulate energy metabolism and control the hemolymph sugar titers (Broughton et al., 2005; Rulifson et al., 2002), fat-body ILPs are the functional equivalent of insulin-like growth factor 1 (IGF1), modulating cell proliferation and organ growth (Okamoto et al., 2009). It has already been suggested that AmILP2 may act as an IGF in the larval fat body of honey bees (Wheeler et al., 2006), but functional evidence for this hypothesis was lacking. Our data now indicate that *AmILP2* knockdown in the fat body does not modulate the hemolymph sugar levels during larval development, but instead *AmILP2* is more related to ovary development and body mass in larvae.

Our study suggests that fat-body *AmILP2* more likely contributes to regulating ovariole development rather than all worker traits, since *AmILP2* knockdown did not significantly affect the expression of other worker traits. Additionally, both JH and ILPs are involved in anti-apoptosis in many other insect species (Schmidt Capella and Hartfelder, 2002; Johnson et al., 2006). Therefore, *AmILP2* knockdown in the fat body may mediate ovary degradation at the end of larval development. Since *AmILP2* knockdown did not change JH titers and the *AmILP2* mRNA level was not significantly correlated with JH titers, *AmILP2* may be indirectly connected with JH through other regulators such as *AmILP1*. Clearly, further studies are needed to test the hypothesis.

Moreover, ovary size and body size in adult bees generally are correlated (Linksvayer et al., 2011), suggesting their regulatory pathways may have common elements. Studies in *Drosophila* showed that fat-body *DILPs* are involved in regulating body size (Okamoto et al., 2009) and fat cell mass (DiAngelo and Birnbaum, 2009). Here, we found that *AmILP1* dsRNA treatment significantly increased *AmILP2* transcript abundance at the whole body level (mainly fat bodies), and also increased body mass of fifth-instar larvae, this leading to infer that fat-body *AmILP2* in honey bee larva may also play a role in determining body mass.

CONCLUSIONS

Summarizing, by means of an RNAi approach we demonstrated that *AmILP2* expressed in the fat body is directly involved in the expression of a queen-type ovary during honey bee caste development, whereas *AmILP1* may do so indirectly via a modulation of JH production in the CA. Thus, we propose that the regulation of worker caste development is not simply a reversed pathway of queen caste development; instead, a network of regulators must cooperate with JH to drive worker development. Furthermore, rather than being an insulin-like peptide, the function of AmILP2 appears to be similar to IGF, regulating cell and organ growth. In agreement with other studies (Kamakura, 2011; Mutti et al., 2011a), our study supports that the IIS pathway has a modulatory, and probably only minor role in caste development of honey bees. Nonetheless, as binding affinities of AmILPs to AmInRs have not yet been investigated in honey bees, the exact role of AmILPs and AmInRs, especially their interactions with other local signaling and endocrine pathways are still puzzling in our understanding of honey bee development and physiology.

863 FIGURE LEGENDS

Fig. 1 AmILP1 and AmILP2 gene knockdown validation in fifth-instar honey bee

larvae. Panel A, B, D, and E show the main effects of AmILP1 dsRNA and

867 AmILP2 dsRNA on AmILP1 and AmILP2 gene expression in a factorial ANOVA.

C and F show the relationships between four treatment groups, as revealed by a Fisher's least significant difference (LSD) *post-hoc* test: the bars from left to right represent *gfp*, *AmILP1 dsRNA*, *AmILP2 dsRNA*, and *AmILP1 dsRNA+AmILP2 dsRNA*. Overall *AmILP1* gene expression was not affected by *AmILP1* dsRNA (A) and *AmILP2* dsRNA (B). Overall *AmILP2* gene expression was not affected by *AmILP1* dsRNA (D), but was significantly reduced by *AmILP2* dsRNA (E). Panel F shows that compared to *gfp* (the first bar): (i) single *AmILP1* dsRNA treatment increased the *AmILP2* expression level; (ii) single *AmILP2* dsRNA in the absence of *AmILP1* dsRNA did not reduce the *AmILP2* mRNA level, (iii) but when combined with an *AmILP1* dsRNA application, *AmILP2* was significantly down-regulated. Data are represented as means ± s.e.m. (n = 15). Different letters (a, b and c) over the bars indicate significant differences between treatments. '0' represents no dsRNA treatment and '1' represents dsRNA treatment.

Fig. 2 Glucose and trehalose levels in the hemolymph of larvae treated with *AmILP1* and *AmILP2* dsRNAs. Panel A, B, D, and E show the main effects of *AmILP1* dsRNA and *AmILP2* dsRNA on glucose and trehalose levels in a factorial ANOVA. C and F show the relationships between four treatment groups by LSD *post-hoc* test: the bars from left to right represent *gfp*, *AmILP1* dsRNA, *AmILP2* dsRNA, and *AmILP1* dsRNA+AmILP2 dsRNA. There was no main effect of either *AmILP1* dsRNA or *AmILP2* dsRNA on glucose (A and B) and trehalose titers (D and E). There was no difference in the four treatment groups with respect to glucose and trehalose titers (C and F). Data are shown as means ± s.e.m. (n = 20). '0' represents no dsRNA treatment and '1' represents dsRNA treatment.

Fig. 3 Hemolymph juvenile hormone (JH) titers in larvae treated with *AmILP1* and *AmILP2* dsRNAs. Panel A, B, D, and E show the main effects of *AmILP1* dsRNA and *AmILP2* dsRNA on JH titers in a factorial ANOVA. C and F show the relationships between four treatment groups as revelaed by a LSD *post-hoc* test:

the bars from left to right represent gfp, AmILP1 dsRNA, AmILP2 dsRNA, and AmILP1 dsRNA+AmILP2 dsRNA. There was a significant main effect of AmILP1 dsRNA on JH titers (A), but no main effect of AmILP2 dsRNA on the JH titer (B). Panel C shows that, compared to gfp, both single AmILP1 dsRNA treatment and AmILP1 dsRNA+AmILp2 dsRNA treatment reduced JH titers, but single AmILP2 dsRNA treatment did not do so, this indicating that only AmILP1 dsRNA contributed to the reduction of JH titers in panel A. Data are represented as means \pm s.e.m. (n = 16-19). Different letters indicate significant differences among treatments. 'O' represents no dsRNA treatment and '1' represents dsRNA treatment.

Fig. 4 Effects of *AmILP1* and *AmILP2* dsRNA treatments on body mass of fifth-instar larvae. Panel A, B, D, and E show the main effects of *AmILP1* dsRNA and *AmILP2* dsRNA on the body mass in a factorial ANOVA. C and F show the relationships between four treatment groups as revealed by a by LSD *post-hoc* test: the bars from left to right represent *gfp, AmILP1* dsRNA, *AmILP2* dsRNA, and *AmILP1* dsRNA+AmILP2 dsRNA. There was no main effect of either *AmILP1* dsRNA or *AmILP2* dsRNA on body mass (A and B). Panel C shows that *AmILP1* dsRNA treatment increased the body mass in the absence of *AmILP2* dsRNA, but the mixture of *AmILP1* dsRNA and *AmILP2* dsRNA tended to reduce body mass. Together with the result of a significant interaction between *AmILP1* dsRNA and *AmILP2* dsRNA treatments on body mass, these results suggest that the effect of *AmILP1* dsRNA on the body mass of the fifth-instar larvae depends on the level of *AmILP2* dsRNA. Data are represented as means ± s.e.m. (n = 20). Different letters indicate significant differences among treatments. '0' represents no dsRNA treatment and '1' represents dsRNA treatment.

Fig. 5 Correlations between larval body mass and *AmILP* expression or JH levels. AmILP1 transcript abundance was positively correlated with body mass (A); AmILP2 transcript abundance was also positively correlated with body mass (B); but JH titers were negatively correlated with body mass (C). Dots represent

individual larvae from all four RNAi treatments; regression lines were obtained by Pearson Correlation Analysis.

Fig. 6 Effects of AmILP1 and AmILP2 dsRNA treatments on ovariole number of newly emerged adults. Panel A, B, D, and E show the main effects of AmILP1 dsRNA and AmILP2 dsRNA on ovariole number in a factorial ANOVA. C and F show the relationships between four treatment groups by LSD post-hoc test: the bars from left to right represent gfp, AmILP1 dsRNA, AmILP2 dsRNA, and AmILP1 dsRNA+AmILP2 dsRNA. Even though there was no main effect of AmILP1 dsRNA on ovariole number (A), ovariole number was significantly reduced by AmILP2 RNAi (B). Panel C shows that compared to gfp, both single AmILP2 dsRNA treatment and AmILP1 dsRNA+AmILP2 dsRNA treatment tended to reduce ovariole number, whereas AmILP1 dsRNA treatment tended to increase ovariole number. Since we did not find a significant interaction between AmILP1 and AmILP2 dsRNA treatments on ovariole number (C), these results suggest that the main effect of AmILP2 dsRNA on ovary development in panel B is independent of AmILP1 dsRNA. Data are represented as means ± s.e.m. (n = 12-27). Different letters indicate significant differences among treatments. '0' represents no dsRNA treatment and '1' represents dsRNA treatment.
